

Summary of Experimental Meson Physics

Kamal K. Seth

Northwestern University, Evanston, Illinois, IL 60208, USA

kseth@northwestern.edu

A summary of the present experimental status of meson physics is presented. The presentation includes the new results presented at the MESON06 workshop, as well as other recent experimental developments in the field.

Keywords: mesons

PACS numbers: 14.40.-n, 13.25.-k, 25.80.-e

1. Introduction

Meson physics is a very broad field, and this workshop covers a very large part of it, with about 25 plenary and 50 parallel talks. I can not possibly attempt to summarize all that. So, I will pick and choose from what was presented, a process which is admittedly very subjective, and add some new and interesting results which were not talked about. I will also update some results which have appeared in print since my talk.

Before I go into physics, let me acknowledge the laboratories and experiments which have contributed to this field, and to this workshop, and briefly mention what is, to the best of my knowledge, their current status. In the following, 'ended' means that data taking has ended, but physics analysis and publications continue.

BEPC (BES II ended, BES III operational in 2007?); BNL (E852 ended, PHOENIX and STAR at RHIC have minor spectroscopy programs); CELSIUS (WASA ended); CERN (Crystal Barrel and OBELIX ended; COMPASS has potential); COSY (ANKE, GEM, TOF operational); DESY (H1, ZEUS, HERMES operational), Fermilab (SELEX and FOCUS ended, Tevatron operational until 2009), Frascati (at DAΦNE; KLOE and DEAR ended, FINUDA and SIDDHARTA operational); GSI (HADES operational, PANDA in 2014?); JLab (CLAS operational, 12 GeV upgrade?); JPARC (operational in 2008?), KEK (PS and Belle (high potential) operational; Bonn (ELSA operational); Mainz (MAMI II operational); SLAC (BaBar (high potential) operational until 2010).

The sum total of the above summary is that while of the many very productive older programs, some have ended, many continue, and new programs (BEPC II,

Fig. 1. Timelike electromagnetic form factors of pion and kaon. The new CLEO results for $|Q^2| = 13.48 \text{ GeV}^2$ are shown with square symbols.

GSI (FAIR), and JPARC) are in the offing. We can therefore have high expectations for continued exciting discoveries in meson physics in the future.

I will begin my summary in the order of the mass hierarchy. Light quark ($n(=u, d)$ and s) mesons, heavy quark (c, b) mesons, and then light/heavy ($c/n, b/n$) mesons. For good measure, I will throw in a gluon or two, and say a few words about glueballs. Finally, I will talk about the recently discovered exotics, about which everybody is excited, but whose nature nobody really knows.

2. Pions and Kaons

Pions and kaons are ancient particles, and one would think that there could not possibly be anything new to learn about them. Actually, there is! One of the most interesting and elementary questions one can ask about a particle is “what does it look like?” To put it in terms of the simplest physical observable, the question becomes, “what do the particle’s electromagnetic form factors look like?” To relate the meson’s form factors to its constituent quarks one needs to invoke perturbative QCD (at least at present), and that means that one needs experimental measurements of form factors at large enough momentum transfers at which pQCD might be expected to be valid. Let us see where we stand both experimentally and theoretically on this issue.

2.1. Electromagnetic Form Factors of Pions and Kaons

Let me recall the great debate about “when is Q^2 large enough to validate pQCD?” which took place in the mid-1980s between Brodsky and colleagues¹, who believed $Q^2 \approx 10 \text{ GeV}^2$ was enough, and Isgur and Llewellyn Smith², who claimed that $Q^2 > 100 \text{ GeV}^2$ would be required. The experimental data for pion form factors used in the debate consisted of barely three data points for $Q^2 > 2 \text{ GeV}^2$ with $\pm 50\%$ errors. We would all agree that perhaps this was “much ado about nothing”. So, what is new?

What is new is the first precision measurements at large timelike momentum transfer ($Q^2 = -s \approx 13.48 \text{ GeV}^2$) of pion and kaon form factors at CLEO³ as shown in Fig. 1^a. The solid curves in the figure show the arbitrarily normalized variation of α_{Strong} with Q^2 . Also shown for the pion are pQCD predictions and QCD sum rule predictions, neither of which come even close to the measured values, which says that here is now something real for theorists to chew on.

3. The S-Wave Mesons

Most of the activity in this category has been confined to the pseudoscalar η and η' mesons. The obvious reason is that accelerators in the 1–3 GeV region can produce them copiously. At this conference, a lot of activity was reported on production of η and η' . Detailed reports were presented on photo- and electro-production measurements being made at Mainz, JLab, and ELSA. We also heard about pion-induced production at BNL, production in e^+e^- collisions at Frascati, in pp collisions at Jülich, and in heavy ion collisions at GSI.

We have an interesting development in the measurements of the mass of η . A recent COSY measurement⁶ reported $M(\eta) = 547.311 \pm 0.028(\text{stat}) \pm 0.032(\text{syst}) \text{ MeV}$, which differs by $\sim 8\sigma$ from an earlier NA38 measurement⁷. $M(\eta) = 547.843.0.030(\text{stat}) \pm 0.041(\text{syst}) \text{ MeV}$. Now we have the report from KLOE⁸ of $M(\eta) = 547.822 \pm 0.005(\text{stat}) \pm 0.069(\text{syst})$, which agrees with NA38 within 0.25σ . The resolution of the $\sim 500 \text{ keV}$ difference in $M(\eta)$ between COSY and NA38/KLOE would normally be only of academic interest, but in this era of meson-meson molecules, it could be important if somebody comes up with a weakly bound molecule of $(\eta + X)$!

The mass of η' is known with a $\pm 140 \text{ keV}$ uncertainty⁹, but so far we have no reports from COSY or KLOE on improved measurements.

KLOE⁸ has also reported the long-sought value of the ratio $R \equiv \mathcal{B}(\phi \rightarrow \gamma\eta')/\mathcal{B}(\phi \rightarrow \gamma\eta) = (4.74 \pm 0.09 \pm 0.20) \times 10^{-3}$, and used it to address the question of the possible glue content of η' . They find it to be $1 - (0.92 \pm 0.06) = (8 \pm 6)\%$. While the numerical value is not significant at this level, it does indicate that the glue content of η' is quite small.

The spectroscopy of the low-mass vectors, the ρ , ω , ϕ has been dominated by the precision measurements of the Novosibirsk SND and CMD2 groups. Measurements of comparable precision are now being reported by KLOE. Hopefully, long-standing problems, like the $> 5 \text{ MeV}$ uncertainty in the ρ mass can be resolved by these new data, although it is my belief that the problem actually lies with the different formalisms for resonance analysis being used.

^aThe $Q^2 F_\pi$ point marked “ J/ψ ” is not a direct measurement, but derived from the measured branching ratio for $J/\psi \rightarrow \pi^+\pi^-$ by Milana et al.⁴. Using the same arguments, I have derived $Q^2 F_K$ ⁵. The agreement of these $Q^2 F_{\pi,K}$ at $Q^2 = 9.6 \text{ GeV}^2$ with the measured values at $Q^2 = 13.5 \text{ GeV}^2$ lends justification to the procedure.

4. The P-Wave Mesons

The P-wave singlets, h_1 and b_1 , have remained inactive for the last fifteen years. The focus of the activity has been on the P-wave triplets, and among them the greatest attention has been drawn by the isosinglet scalars, primarily because $I = 0$, $J^{PC} = 0^{++}$ are also the quantum numbers of the lowest mass glueball. It behooves us, however, to take a look at all three, $^3P_0(0^{++})$, $^3P_1(1^{++})$, $^3P_2(2^{++})$.

The problem common to all the states with masses larger than ~ 1 GeV is excessive crowding. In the 1 GeV interval of mass, 1.25 – 2.25 GeV, according to Godfrey and Isgur¹⁰, 75 (u, d, s) mesons are expected, the average spacing being ~ 15 MeV. The ones which have been observed have widths ranging from 100 – 500 MeV, which means that states overlap, mix, and interfere horribly, and even the most sophisticated partial width analyses of experimental data have a tough time identifying and characterizing (i.e. J^{PC} , branching ratios) the states. The problem is best illustrated by the isospin singlet scalars, the 0^{++} f_0 's.

4.1. The Isosinglet $^3P_0(0^{++})$ or f_0 States

With u, d, s quarks, one expects two isoscalars, f_0 and f'_0 , and an isovector a_0 . The trouble is that there are *five* f_0 's known: $f_0(600)$ or σ , $f_0(980)$, $f_0(1370)$, $f_0(1500)$, and $f_0(1710)$. It has become very important to examine these very carefully because one expects only one more isosinglet 0^{++} state beyond f_0 and f'_0 , and that third state is to be identified with the interesting, and ever elusive, glueball. But we have five! So, any new experimental information on these is most welcome.

4.1.1. The Sigma, or $f_0(600)$: non- $q\bar{q}$ (?)

The sigma has been there for a long time, albeit in the shadows. Its most recent observation is by BES in $J/\psi \rightarrow \omega\sigma$, $\sigma \rightarrow \pi^+\pi^-$, with the result $M(\sigma) = 541 \pm 35$ MeV, $\Gamma(\sigma) = 502 \pm 84$ MeV¹¹. Leutwyler and colleagues¹² interpret the σ as a pole in the $\pi\pi$ scattering amplitude and obtain $M(\sigma) = 441^{+16}_{-8}$ MeV, $\Gamma(\sigma) = 544^{+18}_{-15}$ MeV, and consider its physics to be governed by the Goldstone pions, i.e., the sigma is not a simple $q\bar{q}$ meson. This is consistent with the fact that typical potential model calculations (e.g. Godfrey and Isgur¹⁰) predict the lowest mass f_0 to have a mass of ~ 1.09 GeV. Lattice has so far nothing to say about the σ ; it is still struggling with 250 MeV pions. The fact is that the nature of the σ remains as cloudy as ever, although Pennington¹³ claims that its two photon width precludes its being a tetraquark ($\bar{q}q\bar{q}q$) or a glueball.

Parenthetically, let me mention that BES¹⁴ has confirmed the observation of sigma's strange partner, the **kappa**, previously reported by Fermilab E791¹⁵ in the reaction $D^+ \rightarrow (K^-\pi^+)\pi^+$ with $M(\kappa) = 797 \pm 19 \pm 43$ MeV and $\Gamma(\kappa) = 410 \pm 43 \pm 87$ MeV. In the reaction $J/\psi \rightarrow \bar{K}^*(890) + \kappa$, $\kappa \rightarrow K^+\pi^-$, BES obtains $M(\kappa) = 878 \pm 23^{+64}_{-38}$ MeV and $\Gamma(\kappa) = 499 \pm 52^{+55}_{-87}$ MeV. It will be interesting to see if the κ also emerges from the analysis of $K\pi$ scattering length, a la Leutwyler.

4.1.2. The $f_0(980)$: non- $q\bar{q}$ (?)

We had five scalars, and we wanted to weed out two in order to have left two $|q\bar{q}\rangle$ and one glueball. Well, we appear to have put $f_0(600)$ or σ aside as a pole in the $\pi\pi$ scattering amplitude. We need to remove one more. The axe usually falls on $f_0(980)$. Because $M(K\bar{K}) = 985$ MeV, and $f_0(980)$ strongly couples to $K\bar{K}$, $f_0(980)$, and its cousin $a_0(980)$, are often dismissed as $K\bar{K}$ molecules. This conjecture, or, for example, the recent conjecture¹⁶ that like the σ , $f_0(980)$ is a dynamically generated resonance, make $f_0(980)$ non- $|q\bar{q}\rangle$. However, there is no hard proof, theoretical or experimental, for this assertion. As a matter of fact, as described later, I believe that the systematics of 3P_J states argues against this prejudice.

Despite the fact that $f_0(980)$ is one of the oldest known (since 1973) resonances, and has been observed in numerous experiments, very little quantitative is known about it. An average of the latest measurements by E791¹⁷, Belle¹⁸, BES¹⁹, and KLOE²⁰ gives $M(f_0(980)) = 979 \pm 2$ MeV, and the average of the E791¹⁷ and Belle¹⁸ results gives $\Gamma(f_0(980)) = 45 \pm 5$ MeV. Besides this, we know very little. PDG06 summarizes the decays of $f_0(980)$ to 2π , $2K$, and 2γ as *seen*, *seen*, *seen*, which can be seen as a very unsatisfactory situation. The only quantitative measure we have is that according to BES¹⁹, the partial width for K^+K^- is about 1/3 that for $\pi^+\pi^-$, and when the relative phase space differences are taken into account, the coupling to kaons is about 3 to 4 times larger than that to pions^{19,20}.

4.1.3. The $f_0(1370)$, $f_0(1500)$, and $f_0(1710)$: Glueballs, anyone?

With $f_0(600)$ and $f_0(980)$ banished as non- $|q\bar{q}\rangle$, the scalar field is reduced to the required three, two $|q\bar{q}\rangle$ and one $|gg\rangle$ glueball. Most of the glueball games are played between these three. Despite early over-optimistic searches for ‘pure’ glueballs, it is now generally accepted that ‘pure’ glueballs do not exist. Quantum mechanics dictates that the scalar glueball must mix with the scalar mesons. So, the game now is *how much* $|gg\rangle$ exists in each of the three candidates. Is there a winner? Perhaps not by a landslide, but even so! The answer depends on who you ask, and how they order the *unmixed* $|n\bar{n}\rangle$, $|s\bar{s}\rangle$ and $|gg\rangle$ states. Not much new has been forthcoming in this debate which used to be the talk of the town just a few years ago. The $f_0(1710)$ is now firmly established as being $J^{PC} = 0^{++}$, and it has been found to be healthily populated, along with $f_0(1500)$ in $\bar{p}p$ annihilation at 5.2 GeV/c²¹.

4.2. The isoscalar 3P_J and the $\vec{l} \cdot \vec{s}$ problem

There is a vexing problem with the spin-orbit splitting of the lowest light quark 3P_J states, and I believe that it relates to the non- $|q\bar{q}\rangle$ assignment of $f_0(980)$. Let me elaborate.

The QCD interaction does not depend on quark flavor. The spin-orbit splitting has the same heirarchy for $|n\bar{n}\rangle$, $|c\bar{c}\rangle$ and $|b\bar{b}\rangle$, and it is in the order: 0^{++} (lowest),

Charmonium 3P_J			Light Quark 3P_J		
				<u>1370</u>	0^+
2^+	<u>3556</u>	2^+	2^+	<u>1280</u>	1^+
1^+	<u>3510</u>	1^+	1^+	<u>1240</u>	2^+
				<u>1282</u>	
				<u>1270</u>	
0^+	<u>3415</u>	0^+	0^+	<u>1090</u>	
				<u>980</u>	0^+
	Expt	Theory (GI)		Theory (GI)	Expt

Fig. 2. Systematics of 3P_J levels, (left) $|c\bar{c}\rangle$ charmonium 3P_J states in experiment and theory, (right) low-lying light quark 3P_J states.

1^{++} , 2^{++} . As shown in Fig. 2, it is the order predicted for, and experimentally observed for $|c\bar{c}\rangle$ charmonium, and $|b\bar{b}\rangle$ bottomonium. It is what is predicted for $|n\bar{n}\rangle$, for example by Godfrey and Isgur¹⁰. In assigning $f_0(1370)$ as the 0^+ member of the lowest 3P_J , the PDG would have us believe in the completely inverted order, 2^{++} (lowest), 1^{++} , 0^{++} . This, of course, becomes necessary because the $f_0(980)$ has been dismissed as a non- $|q\bar{q}\rangle$. It is far easier for me to believe that the theoretically predicted 0^{++} at 1090 MeV has been shifted down to 980 MeV by non- $|q\bar{q}\rangle$ admixtures, than to believe that it moves up by ~ 300 MeV to 1370 MeV. In other words, I want to keep alive the possibility of $f_0(980)$ having a substantial component of $|q\bar{q}\rangle$. In doing so, I am entirely aware of the width arguments advanced by Godfrey and Isgur against $f_0(980)$ being $|q\bar{q}\rangle$.

Having dwelt so long on the 0^{++} light-quark mesons, let me simply mention that the situation about 2^{++} tensors is no better. Below 2.4 GeV in mass, six f_2 are predicted by Godfrey and Isgur¹⁰, twelve are claimed by different experiments, and of these only six are considered as well established⁹.

5. The Heavy-Quark Mesons

As stated earlier, the light-quark mesons, have the experimental problem of numerous closely spaced overlapping states with very large widths, and the theoretical problems of being highly relativistic and having too large a value of $\alpha(\text{strong})$ ($\gtrsim 0.6$) to allow application of pQCD. In contrast, the heavy quark mesons are far more tractable, both because they have well-resolved, narrow-width bound states (e.g., for $|c\bar{c}\rangle$ typical level spacing and width are 100 MeV and < 10 MeV, respectively), and tractable relativistic problems ($(v/c)^2 \approx 0.2$ for $|c\bar{c}\rangle$, 0.1 for $|b\bar{b}\rangle$), and small enough $\alpha(\text{strong})$ (≈ 0.3 for $|c\bar{c}\rangle$, ≈ 0.2 for $|b\bar{b}\rangle$) to permit use of pQCD. It follows that if you want to relate meson spectroscopy to the fundamental theory of QCD, you must turn to heavy-quark mesons, and this series of workshops must evolve more and more in that direction.

Fig. 3. Spectrum of $|c\bar{c} >$ charmonium states. The dashed lines indicate states predicted by Godfrey and Isgur¹⁰.

Let me begin by drawing your attention to the level diagram for $|c\bar{c}\rangle$ charmonium states (in Fig. 3). There are eight bound states before the system becomes unstable with respect to decay into open charm $D\bar{D}$ mesons ($D \equiv |c\bar{n}\rangle$) at 3.73 GeV. The $|b\bar{b}\rangle$ bottomonium system is similar, but because of the three-times heavier mass of the b -quark ($m_b \approx 4.5$ GeV, $m_c \approx 1.5$ GeV), it has fourteen bound states before it becomes unstable with respect to decay into open-beauty $B\bar{B}$ mesons ($B \equiv |b\bar{n}\rangle$) at 10.5 GeV.

Let me talk about the experimental situation. The bad news is that many of the facilities which produced most of the recent high precision hadron spectroscopy data have ended. This includes: BNL (E852), CERN (CBarrel), FERMI-LAB (E760/E835). The good news is that new and promising facilities are just coming on, or are on the horizon. These include: DAFNE, GSI (FAIR), JPARC, BEPC II, and CEBAF Upgrade. The (unexpected) good news is that the SLAC and KEK B factories, not built for spectroscopy, have accumulated such huge luminosities that they seem to be capable of making excellent contributions to hadron spectroscopy, almost wherever they choose to.

Progress is made as much by improved precision as by discoveries. So, let me give you a few examples of precision measurements in heavy quark meson spectroscopy.

At Novosibirsk, the mass of J/ψ , $M(J/\psi) = 3096.917 \pm 0.02$ MeV, has been measured, i.e., with an unprecedented precision of 1 part in 3 million²². At CLEO, in a single measurement, $\mathcal{B}(J/\psi \rightarrow e^+e^-)/\mathcal{B}(J/\psi \rightarrow \mu^+\mu^-) = 0.997 \pm 0.013$, lepton universality is confirmed to $\sim 1\%$ ²³. In another measurement, isospin conservation (violation) is confirmed to $\sim 2\%$ (0.5%) by measuring ψ' decay to $\pi^+\pi^-J/\psi$ versus $\pi^0\pi^0J/\psi$ (to π^0J/ψ versus $\eta J/\psi$)²⁴. In the bottomonium sector new measurements at CLEO²⁵ of the leptonic branching ratios of $\Upsilon(1S, 2S, 3S)$ states with a precision of 1–2% have resulted into up to 55% changes in long-accepted values. The precision result, $R \equiv \Gamma_{ee}(1S)/\Gamma_{ee}(2S) = 2.19 \pm 0.03$ can be now used to validate the latest result of unquenched lattice calculation, $R = 1.91 \pm 0.05$. It appears that lattice is getting there. Today $|b\bar{b}\rangle$, tomorrow $|c\bar{c}\rangle$?

Let me move on from improved precision to real discoveries. In the charmonium sector, these have consisted of the discovery of the spin-singlet states $\eta'_c(2^1S_0, 0^{-+})$ and $h_c(1^1P_1, 1^{+-})$. These bound states have long defied attempts to identify them, the main reason being that they are nearly impossible to populate via the vector $\psi'(2^3S_1, 1^{--})$ formed in e^+e^- annihilation. Radiative decay to η'_c is expected to be a very weak M1 transition, and that to h_c is forbidden by charge conjugation. Yet the importance of these spin-singlet states can not be exaggerated. Together with the known spin-triplet states (or their centroid), these provide measures of the QCD hyperfine splitting, and therefore the $q\bar{q}$ **spin-spin interaction**. So, our only hope of learning about the spin-spin interaction rests on the identification of these states of charmonium.

5.1. The Discovery of the $\eta'_c(2^1S_0)$ State of Charmonium

The only hyperfine splitting known in the heavy quarkonia is the mass difference of $1S$ charmonium states, J/ψ and η_c :

$$\Delta M_{hf}(1S) = M(J/\psi) - M(\eta_c) = 3096.9 - (2980.4 \pm 1.2) = 116.5 \pm 1.2 \text{ MeV}$$

A model-independent prediction for the hyperfine splitting of the $2S$ states is that

$$\Delta M_{hf}(2S) = M(\psi') - M(\eta'_c) = \Delta M_{hf}(1S) \times \frac{M^2(\psi')}{M^2(J/\psi)} \times \frac{\Gamma(\psi' \rightarrow e^+e^-)}{\Gamma(J/\psi \rightarrow e^+e^-)} = 68 \pm 2 \text{ MeV}$$

In 1982, the Crystal Ball Collaboration at SLAC claimed identification of η'_c and reported $M(\eta'_c) = 3594 \pm 5$ MeV, which would correspond to $\Delta M_{hf}(2S) = 92 \pm 5$ MeV, about 35% **larger** than expected. Fortunately, or unfortunately, the Crystal Ball observation was never confirmed, and η'_c remained unidentified for 30 years, until now.

In 2002, Belle claimed identification of η'_c in the decay of 45 million B mesons, $B \rightarrow K(K_S K \pi)$ and reported $M(\eta'_c) = 3654 \pm 10$ MeV, which would correspond to $\Delta M_{hf}(2S) = 32 \pm 10$ MeV, a factor **two smaller** than expected and a factor **four** smaller than $\Delta M_{hf}(1S)$. Could this be possible? Well, perhaps! There are two important ways $2S$ states differ from $1S$ states. $1S$ states, with $r \approx 0.4$ f, lie in the Coulombic region (prop. to $1/r$) of the $q\bar{q}$ potential, $V = A/r + Br$, whereas the $2S$

Fig. 4. The invariant mass $M(K_S K \pi)$ spectra from two-photon fusion measurements by CLEO (left) and BaBar (right). The $\eta_c(2S)$ peak is prominent in both spectra.

states, with $r \approx 0.8$ f, lie in the confinement part (prop. to r) of the potential. The spin-spin potential in the two regions could be different. The second difference is that the $2S$ states, particularly ψ' , lie close to the $D\bar{D}$ breakup threshold at 3730 MeV, and can be expected to mix with the continuum as well as higher 1^{--} states. All in all, it is important to nail down η'_c experimentally, and measure its mass accurately.

This was successfully done by CLEO²⁶ and BaBar²⁷ in 2004 by observing η'_c in two-photon fusion, $\gamma\gamma \rightarrow \eta'_c \rightarrow K_S K \pi$. The two observations are shown in Fig. 4. The average of all observations is $M(\eta'_c) = 3638.7 \pm 2.0$ MeV, which leads to $\Delta M_{hf}(2S) = 47.4 \pm 2.0$ MeV, which is almost a factor **2.5 smaller** than $\Delta M_{hf}(1S)$. Explaining this large difference is a challenge to the theorists. The challenge for the experimentalists lies in completing the spectroscopy of η'_c , now that its mass is known.

5.2. The Discovery of the $h_c(1^1P_1)$ State of Charmonium

The interest in identifying h_c is also related to the hyperfine or $\vec{s}_1 \cdot \vec{s}_2$ interaction, but in a different way. In the conventional $q\bar{q}$ potential, the confinement part is scalar, and therefore there is no long-range spin-spin interaction. The $\vec{s}_1 \cdot \vec{s}_2$ interaction is only due to the Coulombic part, and is a contact interaction proportional to the wave function at the origin. In other words, it is finite only for S -states. For P -wave, or higher L states, the interaction is zero. Thus, for $1P$ states, the 1P_1 state should be degenerate with the centroid of the 3P_J states, or

$$\Delta M_{hf}(1P) \equiv \langle M(^3P_J) \rangle - M(^1P_1) = 0$$

There are many ways this prediction could be wrong, viz the simple way of calculating the centroid as $\langle M(^3P_J) \rangle = [5M(^3P_2) + 3M(^3P_1) + M(^3P_0)]/9$ could be (and is) wrong, or the $q\bar{q}$ potential could have a long-range $\vec{s}_1 \cdot \vec{s}_2$ part in it. It is therefore important to experimentally determine $\Delta M_{hf}(1P)$ by identifying the $h_c(1^1P_1)$ state of charmonium. Numerous attempts to identify h_c made during the

Fig. 5. The spectra of π^0 recoil energies in the exclusive analysis of the reaction $\psi' \rightarrow \pi^0$, $h_c \rightarrow \gamma\eta_c$, as measured by CLEO. The peak corresponding to $M(h_c)$ is prominent.

last 35 years had failed. Now, two attempts have succeeded. The Fermilab E835 $\bar{p}p$ annihilation experiment²⁸ has claimed h_c observation at $\sim 3\sigma$ level²⁹ in the reaction $\bar{p}p \rightarrow h_c \rightarrow \gamma\eta_c$ and reported $\Delta M_{hf}(1P) = -0.4 \pm 0.2 \pm 0.2$ MeV. CLEO has reported h_c observation at $> 6\sigma$ level in the reaction $\psi(2S) \rightarrow \pi^0 h_c$, $h_c \rightarrow \gamma\eta_c$. Both inclusive (π^0 and γ detected) and exclusive analyses were made, with the result $\Delta M_{hf}(1P) = +1.0 \pm 0.6 \pm 0.4$ MeV. The exclusive spectrum is shown in Fig. 5. It appears that the $1P$ hyperfine splitting is very small, perhaps even zero.

With the discovery of η'_c and h_c , a milestone has been reached in charmonium spectroscopy. The bound state spectrum is now complete.

6. New Results in Bottomonium Spectroscopy

CLEO is now the only producer of $|b\bar{b}\rangle$ bottomonium spectroscopy results. Besides improving the precision of the branching ratio measurements for the radiative³⁰ and leptonic²⁵ decays of the Upsilon states, CLEO has made the first observation of a non- $\pi\pi$ transition between bottomonium states³¹, and the first observation of a D -state in bottomonium³². Since no bottomonium physics was presented at the Workshop, I will dwell no further on it, and return to meson spectroscopy below 5 GeV.

7. The Unanticipated Discoveries

The renaissance in hadron spectroscopy to which I referred earlier has been triggered by the discovery, or claimed discovery, of a number of unanticipated states. This is very exciting, and also confusing, because the nature of these states is still not understood. In chronological order, the series consists of the pentaquark (Spring8—Jan. 2003), D_{sJ} (BaBar—March 2003), $X(3872)$ (Belle—March 2003), $X, Y, Z(3940)$ (Belle 2005), and $Y(4260)$ (BaBar 2005).

Table 1. Summary of Experimental data for the X, Y, Z states of Belle.

	M (MeV)	N (evts)	Γ (MeV)	Formed in/ Decays to	No decays to	Suggested?
X ⁴⁴	3936(14)	266(63)	39(26)	$e^+e^- \rightarrow J/\psi(X)$	$X \nrightarrow \bar{D}D$	$\eta_c''(2^1S_0)$
Y ⁴⁵	3943(10)	25(7)	15(10)	$X \rightarrow \bar{D}D^*$	$X \nrightarrow \omega J/\psi$	$c\bar{c}$ hybrid
	3943(17)	58(11)	87(34)	$B \rightarrow KY$	$Y \nrightarrow \bar{D}D^*$	
Z ⁴⁶	3929(5)	64(18)	29(10)	$Y \rightarrow \omega J/\psi$	$Y \nrightarrow \bar{D}D^*$	$\chi'_{c2}(2^3P_2)$
				$\gamma\gamma \rightarrow Z$		
				$Z \rightarrow D\bar{D}$	$Z \nrightarrow \bar{D}D^*$	

7.1. The Pentaquark

There have been many reports of the sightings of the pentaquark $\Theta^+(1540)$ and its heavy quark siblings, and even a greater number of reported failures in finding them. Google tells me that there were 123,000 entries for the pentaquark by March 28, 2006, 135,000 by April 10, and 151,000 by the time of this writing in July 25, 2006. This tells you how exciting and intoxicating the idea is, or rather was. See, for example, Refs. 34 and 34. The pentaquark has been on “life-support” for too long. We should let it go—may it rest in peace!

7.2. The Veteran X(3872)

Discovered by Belle³⁵, and quickly confirmed by CDF³⁶, DØ³⁷, and BaBar³⁸, the X(3872) state definitely exists. Its average mass and width are $M(X) = 3871.5 \pm 0.4$ MeV, and $\Gamma(X) \leq 2.3$ MeV, and it decays prominently in $\pi^+\pi^-J/\psi$. What is debatable, however, is “What is it?” Numerous speculations have been made. Is it a charmonium ($C = -, 1^3D_{2,3}$ or 2^1P_1) or ($C = +, 1^1D_2$ or 2^3P_1)³⁹? Is it a $C = +$ charmonium hybrid⁴⁰? Is it a vector glueball mixed with vector charmonium⁴¹, or is it a $\bar{D}^0D^{0*}$ molecule⁴²? A firm determination of the J^{PC} of X(3872) would go a long way in sifting through the above models. Unfortunately, it is difficult to say that any of the claims made so far pin the J^{PC} down unambiguously. A number of reported decays, e.g., $X \rightarrow \gamma J/\psi$, $X \rightarrow \omega J/\psi$, $X \rightarrow \bar{D}^0D^0\pi^0$, which would pin down some of the quantum numbers, suffer from limited statistics, and angular distribution studies and the dipion mass distribution in $X \rightarrow J/\psi\pi^+\pi^-$ appear to be inconclusive. The present toss-up appears to be between $J^{PC} = 1^{++}$ and 2^{-+} , with 1^{++} being a slight favorite. With the goal of pinning down the binding energy of $\bar{D}D^*$ (if it is bound), CLEO has announced⁴³ a preliminary precision determination of the D^0 mass, $M(D^0) = 1864.847 \pm 0.150 \pm 0.200$ MeV, so that the best estimate of the binding energy of the $\bar{D}D^*$ molecule as X is now $E_b \equiv M(\bar{D}^0D^{0*}) - M(X) = +0.31 \pm 0.64$ MeV, which constrains the molecular model considerably more than before. Further constraint would require a more precise measurement of the mass of X.

Fig. 6. The $Y(4260)$ state observed in ISR production, and decay, $Y \rightarrow \pi^+ \pi^- J/\psi$; (left) by BaBar, (right) by CLEO.

7.3. Ringing in Belle: The X , Y , Z States

With huge luminosities ($> 350 \text{ fb}^{-1}$) available to it, Belle has been announcing the discovery of resonance after resonance. By now we have $X(3940 \pm 10)$, $Y(3943 \pm 17)$, and $Z(3929 \pm 5)$, with all masses being consistent with 3935 MeV. The latest results for these states are summarised in Table I. As shown in the table, the errors in the parameters are large enough, and the evidence at least for *non-observations* is tentative enough so that not all three, X , Y , Z , need be distinct and separate states. This is particularly true for X and Z whose widths are similar, and both of them could accomodate different levels of $D\bar{D}$ and $\bar{D}D^*$ decays. It is obvious that lots more experimental data will be needed before the dust settles down. In this respect, it is very disappointing that BaBar, with comparable data sets available to it, has maintained an ominous silence on X , Y , Z . With the excitement these states have generated, one would think that BaBar would jump right in, and prove or disprove the Belle claims!

7.4. BaBar Chimes in: The $Y(4260)$ State

While BaBar has regrettably stayed away from Belle's X , Y , Z states, it has exploited its expertise in ISR (initial state radiation), or RR (radiative return), studies to present another surprise⁴⁷. It has presented evidence for the observation of a broad resonance formed in e^+e^- annihilation following ISR, and decaying into $\pi^+ \pi^- J/\psi$ (see Fig. 6). The parameters of the resonance are $M(Y) = 4259 \pm 8_{-6}^{+2} \text{ MeV}$, and $\Gamma(Y) = 88 \pm 23_{-4}^{+6} \text{ MeV}$. The formation of $Y(4260)$ in ISR and the S-wave dipion mass distribution essentially ensure that $J^{PC}(Y(4260)) = 1^{--}$. This comes as a great surprise, because there is a deep minimum in the $R \equiv \sigma(e^+e^- \rightarrow \text{hadrons})/\sigma(e^+e^- \rightarrow \text{leptons})$ measurement at 4260 MeV, which would militate against the presence of a vector with this mass. It is therefore extremely important to confirm BaBar's observation. This has been done in two new measurements at CLEO.

In the first measurement, CLEO⁴⁸ has confirmed a strong (factor ~ 7) en-

hancement of the $\pi\pi J/\psi$ yield at 4260 MeV compared to the yield at 4160 MeV and 4040 MeV. Lest one argue that enhancement at a single energy point does not confirm a resonance, in a second measurement, CLEO has confirmed the $Y(4260)$ in ISR, exactly the same measurement as BaBar (see Fig. 6). They obtain $M(Y) = 4283^{+17}_{-16} \pm 4$ MeV, and $\Gamma(Y) = 70^{+40}_{-25}$ MeV. The measurement has very small background, and a very clean ($\sim 5\sigma$) signal. So, the $Y(4260)$ 1^{--} state is very real. But, what is it? No charmonium vector is expected with this mass, which deepens the mystery. The usual speculations, such as misplaced charmonium, a $c\bar{c}$ hybrid, a molecule, etc., abound. Clearly, lots more measurements are needed to sift through these speculations.

As a postscript to the discovery of all these new and unanticipated states, and the uncertainty about their nature, let me recall that the discovery of J/ψ ⁴⁹ was followed by a spate of theoretical papers about its nature⁵⁰, most of which, even by famous Nobelists, turned out to be wrong. That is how physics develops.

Let me now move to the non-quarkonium results presented at the workshop.

8. Heavy-Light ($Q\bar{q}$, $\bar{Q}q$)

Here the heavy quark can be either the charm or bottom quark, and the light quark can be $n(=u, d)$, or s . The convention for labeling the quantum numbers of heavy-light mesons is to couple the spin s_Q of the heavy quark with the $j_q = l + s_q$ of the light quark to give the total spin $J = j_q + s_Q$.

8.1. Open-Charm, or $D(=c\bar{n}, c\bar{s})$ Mesons

We have had considerable activity in this sector, with BaBar, Belle and CLEO (particularly in its reincarnation as CLEO-c) making important contributions.

The first exciting news was BaBar's discovery⁵¹ of a new narrow width $D_s^*(c\bar{s})$ meson with $M = 2317$ MeV, $J^P = 0^+$, unexpectedly below the DK threshold. This was followed by the discovery of its $J^+ = 1^+$ partner with $M = 2483$ MeV, below the D^*K threshold, by CLEO⁵². These mesons were expected to lie above their respective thresholds, and to be therefore quite wide. Theoretical suggestions to explain the observed characteristics of these mesons again range from simple $|c\bar{s}\rangle$ to DK^* molecules, to $|c\bar{s}\rangle$ mixed with DK and D^*K continua, and to tetraquark, with no resolution so far. The corresponding non-strange $|c\bar{d}\rangle$ states would be expected at 2217 MeV (0^+) and 2363 MeV (1^+). These are expected to be wide, and have not been firmly identified so far.

Admittedly, the main interest in heavy-light mesons rests in the study of their weak interaction properties, and CLEO-c has made this their major goal. Hopefully precision measurements in this sector will go a long way towards validating the lattice QCD calculations. CLEO has reported preliminary form factor results, $f(D^+) = 222.6 \pm 16.7 \pm_{-3.4}^{+2.8}$ MeV⁵³ and $f(D_s^+) = 282 \pm 16 \pm 7$ MeV⁵⁴. The corresponding predictions from unquenched lattice calculations are $f(D^+) = 201 \pm 3 \pm 17$ MeV

and $f(D_s^+) = 249 \pm 3 \pm 16 \text{ MeV}^{55}$. CLEO has also measured a large number of hadronic and weak decays of D and D_s mesons.

8.2. Open-Beauty, or $B(= b\bar{n}, b\bar{s}, b\bar{c})$ Mesons

This is the domain of CDF and DØ contributions. The latest of their contributions relate to the identification and mass measurements of the excited B -mesons. In the notation $J(j_q)$ the masses are:

CDF: $M(B_1^0) = 5734 \pm 3 \pm 2 \text{ MeV}$, $M(B_2^{*0}) = 5738 \pm 5 \pm 1 \text{ MeV}$,
DØ: $M(B_1^0) = 5721 \pm 3 \pm 5 \text{ MeV}$, $M(B_2^{*0}) = 5746 \pm 5 \pm 5 \text{ MeV}$,
and the four-de-force measurement by CDF is $M(B_c) = 6275.2 \pm 4.3 \pm 2.3 \text{ MeV}$,
which compares with the lattice prediction of $M(B_c) = 6304 \pm 12_{-0}^{+18} \text{ MeV}$.

8.2.1. The *Triumph* of the B -Factories

Since we had a presentation of the latest results on CP violation, let me summarize what we know now. The best values of the angles of the unitary triangle are $\alpha = 105_{-9}^{+15^\circ}$, $\beta = 21.7_{-1.2}^{+1.3^\circ}$, and $\gamma = 65 \pm 20^\circ$. One set of CKM matrix elements is: $|V_{ud}| = 0.97363(26)$, $|V_{us}| = 0.2252(18)$, $|V_{ub}| = 0.004455(33)$, and $|V_{td}|/|V_{ts}| = 0.205(15)$, and, of course, $\sin 2\beta = 0.685 \pm 0.032$.

9. Epilogue

As I mentioned in the beginning, hadron spectroscopy has had a renaissance during the last five years. We have heard about exciting new discoveries at this Workshop, and the future promises many more to come.

On a personal note, I want to thank the organizers and the hosts of this Workshop for a very successful and productive meeting in this wonderful town.

This work was supported by the U.S. Department of Energy.
